Submitted September 4, 2021; accepted April 8, 2022; ePublished April 2022

Objective. The purpose of the study was to compare suicidal ideation among medical and pharmacy students and characterize related symptoms.

Methods. The authors conducted a cross-sectional, retrospective study to compare suicidal ideation among medical and pharmacy students at a single public university during 2009 to 2020. Respondents’ voluntary and anonymous responses to the Interactive Screening Program (ISP) Stress and Depression Questionnaire are reported.

Results. The authors analyzed responses from 619 medical and 214 pharmacy students collected over 11 academic years. There was no significant difference between medical and pharmacy students who endorsed suicidal ideation (13.5% vs. 17.3%, respectively). The PHQ-9 scores were significantly different between medical and pharmacy students with more pharmacy students reporting moderate to severe depression (24.3% for medical vs. 35.1% for pharmacy). Compared to medical students, more pharmacy students also endorsed anhedonia (13.4% vs. 24.3%, respectively), sleep problems (29.6% vs. 42.6%, respectively), and fatigue (46% vs. 64.4%, respectively). Pharmacy students also reported more intense affective states such as “feeling your life is too stressful” and “feeling intensely anxious or having anxiety attacks”. Relationships and physical/mental health/substance abuse were common themes that emerged from the qualitative data.

Conclusion. While there was no significant difference in suicidal ideation between pharmacy and medical students, the prevalence is alarming compared to the general population. More pharmacy students endorsed symptoms of depression and intense affective states that could impair functioning. Future studies may focus on mitigation strategies for suicidal ideation among health professional students.

Keywords: suicidal ideation, pharmacy, medical, students, depression

INTRODUCTION

In 2020, suicide was the twelfth leading cause of death in the United States. 1 In the same year, 47,511 Americans died by suicide and there were an estimated 1,400,000 suicide attempts. 1 2 Rates of suicide have steadily increased from 1999 to 2017 3 and suicide is the second leading cause of death among young adults between the ages of 25 to 34. Depression is a major risk factor for suicide; in a meta-analysis, the prevalence of depression and suicidal ideation among medical students have been estimated to be 27% (95% CI: 24.7-29.9%) and 11% (95% CI: 9.0-13.7%), respectively. 4 This is significantly higher than the national prevalence of 4.7% and 4% for depression and suicidal ideation, respectively, among adults in the United States. 5 In a cross-sectional study of medical and pharmacy students during one academic year, 18% of students met diagnostic criteria for depression. 6 In the same study, more pharmacy students met diagnostic criteria for anxiety and had higher levels of stigma toward mental health treatment. 6 A recent study among pharmacy students showed that one in four pharmacy students reported moderate to severe symptoms of depression and anxiety. 7 While rates of depression and stress levels among health professional students have been reported 6 8, there are currently no studies comparing suicidal ideation, thoughts or behaviors between medical and pharmacy students. In addition, there is limited data for these two cohorts on other known conditions related to suicide risk, such as hopelessness, helplessness, despair, loneliness, and intense affective states.

Clinician burnout, depression and suicidality have garnered national attention along with urgent calls to prioritize clinician emotional and mental health. 9 At the University of California, San Diego (UCSD), the Healer Education
Assessment and Referral (HEAR) program was established in 2008 to destigmatize mental health care and prevent suicide among medical and pharmacy students, trainees and faculty. Implementing the American Foundation for Suicide Prevention’s Interactive Screening Program (ISP), the HEAR program proactively and anonymously screens for suicide risk as a means to provide prompt confidential referrals to those in need. The questionnaire collects information on participants’ mental health, evidence-based suicide risk factors and current mental health treatment.

OBJECTIVE
The authors aimed to compare suicidal ideation, thoughts, plan and behaviors between medical and pharmacy students from anonymous data that were collected between 2009 and 2020. In addition, depressive symptoms, intense affective states, substance use and eating-related behaviors were also examined. The authors also evaluated the qualitative free responses and compared themes for potential stressors associated with depression, and suicidal ideation between the two groups. To our knowledge, this is the first study to compare the rates of suicidal ideation, thoughts, plan and behaviors and associated features between medical and pharmacy students at a health sciences campus.

METHODS
The authors conducted a cross-sectional, retrospective study of the ISP Stress and Depression Questionnaire data that were collected by HEAR counselors between 2009 and 2020. The study authors were not involved in the administration of the surveys and no identifiable information were collected. The study was approved by the UCSD Human Subjects Research Protections office.

Participants in this study were limited to medical and pharmacy students in all levels enrolled between 2009 and 2020. The entering annual budgeted enrollment sizes for medical and pharmacy students during this period were 137 for medical and 60 for pharmacy students. We excluded those who did not complete the survey or completed the survey more than once or reported incongruent demographic information (e.g., age less than feasible for medical and pharmacy students) identified during data cleaning. No additional exclusion criteria applied such as previous mental or physical health problems, age or race.

The Interactive Screening Program (ISP) Stress and Depression Questionnaire is an anonymous questionnaire completed online by the student. The ISP has been identified by the Suicide Prevention Resource Center Best Practices Registry for Suicide Prevention for identifying students in or verging on suicide or depression. Since 2008, the HEAR committee has administered the ISP Stress and Depression Questionnaire to all faculty and students at the schools of medicine and pharmacy on an annual (January of each year) and voluntary basis. The questionnaire includes items modified from the Patient Health Questionnaire (PHQ-9) as well as questions surrounding anxiety, suicidal ideation, medication and substance use and eating behaviors.

Suicidal ideation was measured using four questions, “had thoughts about taking your own life”, “planned ways of taking your own life”, “done things to hurt yourself”, and “had thoughts of death or physically harming yourself” (last question taken from the PHQ-9 suicide ideation measure). Students were grouped into two categories, suicidal or non-suicidal, with students classified as suicidal if they endorsed even one of the four items in the previous two weeks. Endorsement was defined as responding “some of the time”, “a lot of the time” or “most of the time”. An additional item asked participants to answer “Yes” or “No” if they had ever had a past suicide attempt.

The PHQ-9 is a commonly used instrument for screening, monitoring and measuring the severity of depression. This questionnaire consists of 9 questions which incorporate DSM-5 diagnostic criteria and major signs or symptoms of depression. The PHQ-9 scores range from 0-27 where cutoffs for scoring for depression severity are as follows: 0-4 (none), 5-9 (mild), 10-14 (moderate), 15-19 (moderately severe) and 20-27 (severe). The ISP uses the PHQ-9 questions but changed the response scale (0 = not at all; 1 = several days; 2 = more than half the days; 3 = nearly every day) to be consistent with the rest of the ISP questionnaire items (0 = not at all; 1 = some of the time; 2 = a lot of the time; 3 = most or all of the time). The PHQ-8 represents all of the PHQ-9 questions, without the suicidality item, that was used for the analysis of suicidal ideation.

In addition to the PHQ-9, students were asked 10 questions about intense affective states including anxiety, irritability, feeling intensely lonely or angry and feeling hopeless or “out of control”. Students were asked, “During the last 4 weeks, how often have you been bothered by any of the following?” with response options of “not at all”, “some of the time”, “a lot of the time”, and “most or all of the time” where any positive response other than “not at all” were considered endorsement. Students were asked
three questions about unhealthy eating behaviors or thoughts using the same Likert scale. Finally, students were asked about current mental health treatments. A series of demographic questions at the end of the survey gathered information on age, race, gender, school (medical vs. pharmacy) and year in school.

The ISP Stress and Depression Questionnaire was emailed to the school email addresses of all students attending either the medical or pharmacy school (regardless of year of study) during Fall or Winter Quarter of each year during 2009 through 2020. Students were not required or given an incentive to complete the survey but were informed of the potential positive outcomes that could result in their honest participation, including receiving a personalized risk analysis and option to engage anonymously with a program counselor. If the risk analysis indicates a high risk for suicidality, a program counselor will reach out to the student through an anonymous portal to provide assistance (counseling, referral). For such a program to be successful, the need for screening and identifying individuals at risk for suicidality is balanced by the need for anonymity of disclosing such sensitive information. All information received was kept anonymous through a unique identifier that the participant created upon completion of the survey.

A section for free responses was available for students to explain any stressful situations the student might be experiencing during that time in school. The free text responses included the prompt, “Please take a minute to let us know about anything that has been particularly stressful for you lately – death of a loved one, relationship break-up, academic stressors, family or money problems, difficulty with your living situation – or anything else that might be contributing to how you are feeling.” Two investigators coded the free text responses independently using a pre-determined set of themes. During the coding process, additional themes emerged which were then used to recode the free text responses.

Group comparisons were exploratory and analyzed using t-test and Chi-square/Fisher’s exact tests for linear and nominal data, respectively. Qualitative data were analyzed using Microsoft Excel (2016). All quantitative data were analyzed using IBM SPSS, Version 25 (Armonk, NY).

RESULTS

Quantitative Data

A total of 833 (619 medical and 214 pharmacy) students responded to the ISP Stress and Depression Questionnaire during 2009-2020. The response rates for medical and pharmacy students were 30.1% (619/2057) and 25.5% (214/840), respectively. We excluded responses from 22 medical and 12 pharmacy student responses due to repeat submissions or incongruence to program and year, which reduced our sample to 799 student responses (597 medical, 202 pharmacy students). There were a higher percentage of female student respondents in the pharmacy school compared to medical (78.5% vs. 57.9%, F = 27.31, p<.001). The average ages of respondents were 25.6 ± 3.10 years old for medical students and 24.7 ± 2.81 years old for pharmacy students (F = 10.98, p=.001) (Table 1). In medical school, White student respondents were predominant (43.5%) versus Asian student respondents in pharmacy school (59.5%) (F = 53.15, p<.001).

We found no significant differences between medical students and pharmacy students with respect to suicidal ideation. Overall, 13.5% (n=80) of medical students and 17.3% (n=35) of pharmacy students endorsed at least one suicidal ideation item for at least some of the time in the last two weeks (p=.202) (Figure 1). There were differences between medical and pharmacy students for the four items related to suicidal ideation; while not statistically significant, 11.4% and 15.8% of medical and pharmacy students, respectively, endorsed having self-injurious behavior in the previous two weeks.

The PHQ-9 total scores for medical and pharmacy students were 6.68 (±4.76) and 8.66 (±5.56), respectively (p<.001). The PHQ-8 total scores (without suicidal ideation item) for medical and pharmacy students were 6.56 (±4.53) and 8.39 (±5.21), respectively (p<.001). More pharmacy students reported having moderate to severe depression (35.1%) than medical students (24.3%, p=.001).

There were statistically significant differences in six of eight individual items of the PHQ-8 between medical and pharmacy students (Table 2). For example, more pharmacy students endorsed anhedonia (24.3% vs. 13.4%, p=.001), sleep difficulties (42.6% vs. 29.6%, p=.001), decreased concentration (30.7% vs. 16.9%, p<.001) and feeling tired (64.4% vs. 46%, p<.001), compared to medical students. In general, greater number of pharmacy students endorsed all symptoms of major depression compared to medical students.

With respect to the intense affective state items, more pharmacy students than medical students endorsed “feeling nervous or worrying a lot” (41.6% medical, 57.9% pharmacy, p<.001), “feeling annoyed (40.3% for pharmacy, 25.5% for medical, p<.001), “feeling your life is too stressful” (36.0% medical, 53.7% pharmacy, p<.001), “feeling intensely anxious or having anxiety attacks” (11.1% medical, 23.9% pharmacy, p<.001), “feeling intensely angry (4.4% for medical, 9.0% for pharmacy, p=.019), “feeling hopeless (11.1% for medical students, 17.9% for pharmacy, p=.015), and
“feeling desperate” (9.5% for medical, 15.9% for pharmacy, \( p = .019 \)) (Table 3). There were no significant differences between medical and pharmacy students across other items.

While there were no differences between pharmacy and medical students regarding substance use and eating-related thoughts and behaviors, approximately one-fifth of medical and pharmacy students endorsed drinking alcohol more than usual from baseline (20.4% for medical, 19.3% for pharmacy, \( p = .762 \)), and felt that they were “drinking too much” (15.6% of medical and 12.9% of pharmacy students (\( p = .363 \))) (Table 4). Approximately 40% of pharmacy and medical students endorsed feeling that they could not control what or how much they eat (38.4% medical, 46.0% pharmacy, \( p = .057 \)) or feeling concerned about staying thin or losing weight (42.7% medical, 48.5% pharmacy, \( p = .164 \)).

Of the respondents, 18.9% of medical and 15.9% of pharmacy students reported being in treatment (\( p = .397 \)). For the types of treatment, students reported taking medication(s) for anxiety or depression (9.7% for medical, 10.0% for pharmacy, \( p = .892 \)) and receiving counseling (14.1% for medical and 10.4% for pharmacy, \( p = .188 \)).

**Qualitative Data**

Of the 597 medical and 202 pharmacy students, 252 (42.2%) and 99 (49.0%) students, respectively, entered a free response. Upon analysis of our qualitative data, 9 themes emerged. The 9 themes along with examples of issues reported by students included: 1) family: any stress due to a loss of a family member, health issues with family members, difficulty spending time, connecting to or feelings of disapproval or pressure from family; 2) financial: stress induced by the worry of loans, fees, or other impending monetary issues; 3) relationship: worry or stress due to difficulties with a present or past relationship or stress from the lack of relationship; 4) schoolwork: stress from rotations, residency matching, course load, application processes, future job prospects post-graduation, career path in general including whether medicine/pharmacy was the “right choice”; 5) religion/race/sexuality: stress from difficulties finding acceptance for religion, race, or sexuality from peers or family members; 6) physical or mental health: any underlying, developing health conditions, in addition to poor eating, sleeping, or exercise patterns, issues with body image, substance use; 7) social support: lack of social support, not “fitting in”, difficulty with transition; 8) work-life balance; 9) other (not all listed to protect anonymity): cultural differences, lack of autonomy, self-confidence/imposter syndrome, and living situation.

For pharmacy students, the three most common themes that emerged in order of decreasing frequency were 1) work-life balance, 2) physical/mental health and substance abuse and 3) relationship. For medical students, the most common themes in order of decreasing frequency were 1) academic, 2) relationship and 3) physical/mental health and substance abuse.

**DISCUSSION**

The prevalence of depression and suicidal thoughts that have been previously reported among medical students are alarming4,13 and higher than the reported annual prevalence of 4% for suicidal ideation in adults in the United States.5 This is the first report that compares depression, suicidal ideation and other risk factors between pharmacy and medical students over an 11-year period. Mean PHQ-9 scores from this study suggest that pharmacy students are more depressed than medical students. In a study by Fischbein et al, 18% of pharmacy and medical students met clinical cut-offs for depression4 which were less than rates found in this study of 24.3% and 35.1% of medical and pharmacy students who met criteria for moderate to severe depression. While not statistically significant, current data also suggest trends towards higher suicide risk (especially with respect to suicide “plan” and “behavior”) among pharmacy students compared to medical students. Previous studies have shown that non-suicidal self-injury (NSSI) is associated with a 3.46 fold increased risk of suicidal attempts later on in the life of a student.14 Another study showed that NSSI may suggest higher risk of suicide attempt in adolescents and college students not reporting suicidal ideation compared to those endorsing suicidal ideation in the past year.15 The current ISP does not directly query NSSI, but instead asks about “past attempts” and “self-injurious behavior (SIB).” It is unknown whether the SIB occurred recently or in a distant past based upon the cross-sectional nature of the ISP administrations examined in this study. Kieckens and colleagues found that recent NSSI was associated with a dose-response relationship with the number of mental disorders and suicidal thoughts and behaviors in a 12-month period.16 In Germany, a lifetime prevalence of NSSI was estimated to be 14.3% for NSSI and 1.5% for suicide attempt among medical students.17

Data surrounding the prevalence of depression and suicidal ideation among pharmacy students are limited, although they are emerging. In 2017, the American Association of Colleges of Pharmacy, representing all schools/colleges of pharmacy in U.S. and Canada, issued a policy statement stating that “AACP encourages schools and colleges of pharmacy to proactively promote overall wellness and stress management techniques to students, faculty, and staff”.18 AACP convened two national conferences (Strategies to Promote a Culture of Well-being among Students and
Faculty) to draw attention to the issue of student well-being, burnout, depression, and suicidality at schools/colleges of pharmacy across the academy. Pharmacy institutions and academics gathered to brainstorm ways to mitigate the growing and disturbing trends in student suicide and referrals to counseling/psychiatric care. Suicide generally is caused by the convergence of multiple risk factors — the most common being untreated or inadequately managed mental health conditions. At this public university, the schools of medicine and pharmacy, employ a variety of strategies and resources to enhance student well-being such as improved access to psychiatric care, drop-in counseling services and wellness symposia along with annual screenings. At the School of Pharmacy, quality of life surveys are also administered each year for all students, and a faculty guide has been developed for students in distress as a resource. While mental health resources are important, this current study suggests that pressures within the program to maintain work-life balance may also be contributors for student well-being.

Pharmacy students also reported higher levels of anhedonia, impaired sleep and decreased concentration compared to medical students. It should also be noted that more than 60% of medical and pharmacy students endorsed “feeling tired or having little energy”. Levey reported that tiredness and lack of energy are both risk factors for depression and suicide ideation in medical residents. More pharmacy students reported fatigue compared to medical students that could be explained by the fact that most pharmacy students at this institution are employed during pharmacy school. Employment is encouraged for pharmacy students so that they obtain hands-on skills and preparation for careers, especially if they do not pursue post-graduate training (that is not currently required for pharmacists). More pharmacy students also endorsed “feeling nervous”, “feeling easily annoyed or irritable” and “feeling your life is too stressful” compared to medical students. There has been a change in the pharmacy workforce that may generate nervousness and high stress. Issues such as insufficient number of residency positions compared to the number of applicants, lack of job growth, and shortage of jobs along with decreased salary in some sectors have all led to uncertainties in the pharmacy profession. Recent Pharmacy Workforce study in 2019 showed that more pharmacists rated their workload as “high” or “excessively high” compared to previous years, especially in the retail pharmacy setting and that students had higher debt at the time of graduation.

In a study of various health professions, stress has been directly linked to depression and suicidal ideation and is detrimental to physical and mental health that can lead to poor performance, lowered self-esteem and self-value. Among medical students, chronic stress and anxiety negatively affected mental health and were associated with suicidal ideation.

For medical students, the high rate of response for academic difficulties is consistent with previously reported risk factors for suicidal ideation that include poor performance, difficulty coping with long study hours, and emotional distress brought on from failure in examinations. In addition, stressors for medical students are commonly found to be heavy course loads, pressures of family and society to be academically flawless, and difficulty accepting lower grades or academic standings from undergraduate years. To our knowledge, risk factors correlating with depression and/or suicidality among pharmacy students have yet to be described.

In the qualitative data, for both pharmacy and medical students, relationship and physical/mental health and substance abuse were common themes between the two professional student groups. Relationship issues are not surprising considering the age of the students (mid-20’s) who are at prime ages of building relationships with partners or adjusting to relationship issues with the rigors of pharmacy or medical school academic life. Per recent review, incorporating peer and faculty-led support to build a well-being curriculum are needed to prevent and manage distress and depression that students and practitioners may develop.

About a fifth of both medical and pharmacy students reported drinking alcohol more than usual and more than a third of students reported eating-related behaviors that could be concerning. Increased alcohol consumption among medical students have been previously reported. These results emphasize the need for availability and extent of student health services at all pharmacy and medical schools. The combined risk of academic rigors along with transition difficulties (ie, geographical, social structure, housing) associated with health professional school students cannot be ignored, especially given that the emergence of depression, anxiety disorders, and other physical ailments often occur during the years between 20s-30s. Substance use has been shown to be a risk factor for burnout and suicidality among health professional students. Self-medication for anxiety, sleep disorders and other symptoms that are untreated have been shown to increase the risk for suicide among physicians.

The majority of pharmacy student respondents were female, which is representative of pharmacy students nationwide, with a national percentage of 63% female. During 2014 to 2019, approximately 50% of enrolled medical students were female. Of the pharmacy students, Asian or Pacific Islander and White students were the majority in the study while nationally, Asian students make up only 28% of students (Table 1). Most of the medical students in this sample were White or Asian/Pacific Islander students, which somewhat resembles the demographic makeup of medical
students across the country. According to AAMC, medical students are comprised of 54% White and 21% Asians. In this study sample, Asian and female students were overrepresented in both pharmacy and medical schools. The average age among both pharmacy and medical students were similar but statistically different. The average ages are consistent with profile of medical and pharmacy students across the country. While studies have not conclusively linked race/ethnicity with rates in burnout among medical and pharmacy students, authors have found that minority medical students experience discrimination, prejudice and isolation, that may result in burnout.

The study was limited by the relatively low response rated for both cohorts. Therefore, the prevalence rates found in this sample might be over- or under-representations of the actual rates in the target population if we consider the possibility that more depressed students chose to complete the survey or that fewer depressed students filled it out for fear of stigma or lack of motivation. Shea and colleagues surveyed University of Pennsylvania medical students and found that only one fourth of those who were depressed had sought treatment. In addition to stigma and fear of disclosure, students cited reasons such as lack of time and cost. Our study was also limited to the students attending the School of Medicine and School of Pharmacy at one public university, so generalizability to all medical and pharmacy students is limited. In addition, our questionnaire was purely voluntary, therefore we faced sampling bias in which students with suicidal ideation could opt out of responding to the survey. The study was also cross-sectional in nature; therefore, students’ report of suicidal ideation could have changed after they have responded to the survey. It should be noted, however, that the data presented here represent 11 years of survey administration.

CONCLUSION

The rates of suicidal ideation and depressive symptoms among medical and pharmacy students in this study are alarming. Future investigations should focus on replicating this study with additional cohorts of medical, pharmacy and other health professional students in different geographic regions. With increased samples, the potential contribution of socioeconomic status and other risk factors may be further explored. The authors hope that this will be the next step to more mental health and wellbeing studies in all fields of medicine. With further insights, educators can proactively intervene and support health professionals who are affected by depression, other mental illness, and suicidal thoughts, behaviors and plans. Ultimately, the goal is to empower health communities to decrease the suffering and tragic loss of life caused by suicide.
